Received: 23 December 2018 / Accepted: 09 July 2019 / Published online: 14 July 2019

**Abstract** The present study deals with molluscan accumulations of the Sokolowia horizon, which is a key-bed in the middle Eocene of the Kalateh section (Ziarat Formation, Eastern Alborz, Iran). The age of this “key horizon” is attributed to Bartonian based on presence of larger benthic foraminifera species such as Namulittes lyelli (D’Archic & Haime), Orbitocyclus zitteli (Checchia-Rispoli) and Asterocyclina stella stella (Gümbel) immediately below it. The paleogeographic distribution of Sokolowia occurrence from Tarim Basin in eastern Central Asia to the Transylvanian Basin in southeastern Europe indicates a middle Eocene seaway along the southern margin of an Eurasian epeiricental sea. In particular, the comparison of middle Paleogene sequences in different Central Asian regions reveals an apparent similarity between those basins pointing to their genetic relationship.

**Keywords:** Sokolowia; larger benthic foraminifera; Central Asia; Eastern Alborz

**INTRODUCTION**

During the Paleogene (65 to 23 Ma) the Earth experienced paleoclimatical and paleobiological variations, such as numerous extinction events, extreme temperature fluctuations, and changes in the diversity and frequency of different species (Thomas, 2003; Zachos et al., 2003; Gradstein et al., 2004). Among the various groups of organisms, oyster bivalves are the most abundant macrofossils in the Cenozoic shallow water sediments of Central Asian basins (see Berizzi Quarto di Palo, 1970; Lan, 1997; Bosboom et al., 2011). Despite not as diverse as other bivalve groups, oysters include some excellent index species with short time ranges between evolutionary appearance and extinction, being therefore very useful biostratigraphic tools in shallow marine settings (Griffin et al., 2005; Bosboom et al., 2015). Besides, many authors consider oysters for important proxies for paleoenvironmental conditions in epicontinental basins, however, only few studies have been conducted throughout the Tethys area over the Eocene time (Lan, 1997; Rusu et al., 2004; Griffin et al., 2005; Bosboom et al., 2011). The main objective of the present study is to establish a biostratigraphic correlation of the Sokolowia horizon from the Kalateh section (Ziarat Formation, Eastern Alborz) with the Central Asian basins to the East and the Transylvanian Basin to the West. In order to determine the age of the “Sokolowia horizon” in the studied section, biostratigraphic examination of larger benthic foraminifera was conducted in an earlier study (Hadi et al. 2019). That new data, contribute significantly to a more precise reconstruction of the paleo-sea way across the proto-Paratethys between the eastern parts of Central Asia (Tarim, Ferghana and Afghan-Tajik basins) and the Southeastern Europe (Transylvanian Basin) during the middle to late Eocene.

**GEOLOGICAL SETTING AND STRATIGRAPHY**

Being a part of the largest mountain belt of the Alpine-Himalayan system the Iranian plateau has been subdivided into eight sedimentary-structural provinces characterized by different tectonic and sedimentary events (Stöcklin, 1968; Aghanabati, 2004), (Fig. 1a): (1) Alborz, (2) Central Iran, (3) Zagros, (4) Kopet-Dagh, (5) Lut, (6) Sanandaj-Sirjan, (7) Urmieh- Dokhtar (Sahand-Bazman) magmatic arc, and (8) Makran (Fig. 1b). In northern Iran the Alborz range (about 600 km long and 100 km wide) is one of the most investigated geological-structural zones. The E-W trending Alborz mountains belt as one of the most tectonically active zone in the Alpine-Himalayan orogenic belt is located between the Caspian Sea Basin to the north and the Central Iran Basin to the south. The Alborz range spreads westward into the Pontides Arc (in easternmost Turkey) and the Lesser Caucasus (in Georgia and Armenia) (Asiabanha & Foden, 2012). The Alborz region is a tectonically active zone formed due to the collision between the Gondwana and the Eurasian plate after the closure of Paleo-Tethys Ocean in the Permo-Triassic time (Sengör & Burker, 1978; Stampfli et al., 1991). Following the northward subduction of the Palaeo-Tethys, the Alborz margin, divided into western, central, and eastern sector, was affected by the Cimmerian and Alpine orogenic phases (Alavi, 1996). Generally, in the southern Alborz flank three lithostratigraphic formations are distinguished (Dellenbach, 1964; Stöcklin, 1972): (1) the Fajan Formation (Paleocene-early Eocene) is mainly composed of continental, terrestrial shales, red conglomerates and sandstones, (2) the Ziarat Formation (early-middle Eocene) mainly comprises foraminiferal limestones, sandy limestones, silty and calcareous marls, and (3) the Karaj Formation (middle Eocene) characterized a more than 3000 m-thick succession of shale, sandstone, tuffaceous sandstone and gypsum.

The Sokolowia shell accumulations have been studied in the Kalateh section, which belongs to the Ziarat Formation (middle Eocene). The section is located 5 km northwest of Kalateh village and 40 km northwest of Damghan city. It is situated in the Gorgan 1/250000 quadrangle (sheet-7855; after Sharabi, 1990) (coordinates: 36° 22' 50" N; 59° 23' 54" E) (Fig. 1c). The first note on the shallow marine deposits of the Kalateh section and its mollusk fauna was provided by Grewingk (1853), citing its position as valley to Surt (=Orost) near Namakeh (village N of Kalateh). From material collected there by botanist Fedor A. Buhse he erected the new species termed Gryphea buhsi (=Sokolowia buhsi). The Kalateh section (Fig. 2) consists of 25 m thick nummulitic and coralline red algal limestone, which is superposed by a 7 m thick interval of silty marl and marly limestone intercalated by Sokolowia accumulations. The lower boundary of Sokolowia marly limestone is sharp and erosional with nummulitic and coralline red algal limestone. The lower part of the Sokolowia accumulation is characterized by articulated and low fragmentation shells in silty mudstone matrix. The upper part is characterized by disarticulated, convex-up, highly fragmented and poorly sorted large Sokolowia with normal grading, sharp and erosional base in the uppermost part. Here, we have three types of shell concentrations with thickness, including (1) 40-60 cm, (2) ~1.5 m, and (3) 0.5-1 m. Larger benthic foraminifera from the topmost part of the lower unit, about 1.5 m below the lowermost Sokolowia accumulation (Fig. 2) indicate biostratigraphic correlation with the zones SBZ17-SBZ18b suggesting the Bartonian age (Hadi et al. 2019).

MATERIALS AND METHODS

Oyster bivalves pertaining to the Ziarat Formation of the Kalateh section were collected with well-preserved for systematic descriptions from silty marl and marly limestone deposits. Thirty specimens for oysters were investigated and photographed by a Cannon 60D camera and macro lens L100. Also, the identification of the genus and species are mainly based on taxonomic descriptions given by Berizzi Quarto di Palo (1970), Stenzel (1971), Lan & Wei (1995). The material is housed in the collection at Ferdowsi University of Mashhad by M. Hadi.

Material: eighteen left valves, twelve right valves, MASSH 0001 - MASSH 0030.
Stratigraphic occurrence in the Alborz Basin: Ziarat Formation, Kalateh Section: Horizon 1 at 26.5 m from the base; horizon 2 at 27.5 m from the base; horizon 3 at 29 m from the base. Dimensions: (left valve): length (L) 54 mm, height (H) 79 mm, shell thickness 46 mm, (right valve): length (L) 32 mm, height (H) 43 mm, shell thickness 11 mm.

Description: Our Sokolowia specimens are characterized by well-preserved, medium to large sized, inflated, subequilateral, thick walled shells, homoeomorphic with Gryphaea (grypsh shaped). The left valve is strongly convex with a narrow, high and recurved umbo. The ligamental area is oblique, the interior shell surface smooth. In the ovoid internal cavity the reniform and semicircular muscle scar is placed near its center. The right valve is inequilateral, flattened, concave and triangular in outline, without ribs, but with fine concentric growth lines. The left valve is covered partially or fully with weak to strong radial ribs; they are slender and densely spaced. In the umbonal region, they are a lot and in short distance, but almost disappear toward ventral margin part and only concentric lamellae can be visible.

Remarks: Ornamentsations of the Sokolowia buhsii morph. Buhssii is present in the left valve from the umbonal region up to the ventral margin, whilst in the Sokolowia buhsii morph. Esterhazyi they are limited to the umbonal region, almost disappearing toward the ventral margin where concentric lamellae become prominent (Fig. 3). Note, that also Stenzel (1971) considered latter differences as morphological variation of the same species.

DISCUSSION

Paleobiology of Sokolowia

Sokolowia is probably one of the descendants of Turkestrea (Vyalov, 1936; Griffin et al., 2005). It shows a very rapid evolution, short duration and has a provincial paleobiogeographic extent, being restricted to the middle-late Eocene of Central Asia and Romania (Berizzi Quarto di Palo, 1970; Stenzel, 1971; Lan, 1997; Rusu et al., 2004; Bosboom et al., 2011; Salahi & Vahidinia, 2011). Sokolowia is known as a good environmental proxy from Eocene successions having great importance in the reconstruction of sedimentary environments, especially in relation to paleo-depth, water depth, salinity and substrate (Lan, 1997; Bougeois et al., 2016; Bosboom et al., 2011).

From paleoecological perspective, Sokolowia was an epibenthic and suspension feeder, characterized by massive and large-sized shells. It was well adapted to solitary life in the subtidal shallow marine water conditions, with their left valves lying on soft muddy and sandy bottoms, partially sunk into the substratum, whereas their flat right valves attained nearly horizontal position (Stenzel, 1971; Lan, 1997; Rusu et al., 2004; Bosboom et al., 2011). Several authors (e.g. Stenzel, 1971; Lan, 1997; Meszaros et al., 1987) pointed out that Sokolowia lived in normal salinity conditions in a deeper part of the shallow water zone under the influence of wave action. Their thick-walled, heavy shells provided them practically immovable by water turbulence at the sea bottom.

Age of the Sokolowia horizons in NE Iran

The maximum age of the Sokolowia buhsii and S. esterhazyi horizons in the Kalateh section is Bartonian. Hadi et al. (2019), established this age for the preceding lithostratigraphic unit in the section bearing larger perforate hyaline foraminifera such as orthophragmines (Orbitoclypeus and Asterocyclina) and nummulitid assemblages (Nummulites) (Fig. 2). Nummulitid accumulations dominated by Nummulites iavelli (Fig. 4a-e) associated with A-forms of Orbitoclypeus zitteli (Fig. 4f-h) and Asterocyclina stella stella (Fig. 4i) along with other biogenic components within this interval including small benthic foraminifera (miliolids and rotaliids), larger benthic foraminifera such as N. cf. deshayesi, Operculina sp., and encrusting foraminifera (Carpenteria sp. and Gyroidinella magna) allow a precise biostratigraphic correlation with the SBZ17-SBZ18b of Serra-Kiel et al. (1998) and Less and Özcan (2012). Because, corresponding foraminifera are missing in the Sokolowia bearing unit in the study section, its upper age limit remains uncertain (Fig. 2).

Still, the “Sokolowia horizon” from the Alborz region can be well compared with such accumulations from the Khangiran Formation in the Kopet-Dagh basin (NE Iran), in which Salahi & Vahidinia (2011) considered the “Sokolowia horizon” of the Lutetian-Bartonian age. Thus, we assume also for the corresponding horizon of the Kalateh section the Bartonian age.

Correlation of the Sokolowia horizon in adjacent basins

Sokolowia had extensive paleogeographic distribution throughout the Central Asian Basin System representing...

Sokolowia horizon of the Ziarat Formation (eastern Alborz, Iran): biostratigraphic and paleogeographic implications

the eastern and central part of the proto-Para Tethys epicontinental sea during the middle to late Eocene time-span (Bosboom et al., 2015). Therefore, they can be considered as stratigraphic index fossils diagnostic for that interval. Besides, Sokolowia has always been considered as an important macrofossil for determining the age of formations in central Asia in marine deposits (e.g., Vyalov, 1937, 1948; Osipova, 1958; Lan, 1997). The presence of the Sokolowia accumulations in the Ferghana basin in the eastern of Uzbekistan, the Amu-Darya basin of Turkmenistan and Uzbekistan as well as the northwest of Afghanistan demonstrates a widespread dispersal in central Asian basins during the late Lutetian to the early Priabonian (e.g. Berizi Quarto di Palo, 1970; Ulmishek, 2004). Further east, in the Tarim Basin (NW China) the “Sokolowia horizon” was also reported from the late Lutetian to early Priabonian Kalatar Formation by Bosboom et al. (2011, 2015) and Bougeois et al. (2016). Therefore, the Eocene deposits containing Sokolowia in the Central Asian region, including the Kopet-Dagh, Amu-Darya, Syr-Darya, Afghan-Tajik, Ferghana, Tarim and Alborz basins comprise the late Lutetian-early Priabonian time-interval.

Conspicuously, this prominent Central Asian key-horizon is known from Europe only in the Transylvanian Basin of western Romania (Rusu et al., 2004). There, the Sokolowia eszterhazyi horizon is situated below the Nummulites perforatus accumulations indicating the late Lutetian-early Bartonian age. It belongs to the Capuşu Formation, attributed to the late Lutetian-early Bartonian biozones P12 (planktonic foraminifera) and NP16 (calcareous nannoplankton) (Rusu et al, 2004; Gradstein et al., 2004). In this unit, Odin (1978) reported the age of 41.2 ± 2.1 Ma for Sokolowia eszterhazyi beds by radiometric date (K/Ar analyses).

The aforementioned reports show the “Sokolowia horizon” as a valuable marker bed, which can be well used for the correlation of adjacent basins in the vast region from the easternmost central Asia (China) to the southeastern Europe (Romania) (Berizi Quarto di Palo, 1970;
Mehdi Hadi, Amir Salahi, Yaghub Nasiri & Hossein Mosaddegh

Dzhalilov et al., 1982; Lan, 1997; Rusu et al., 2004; Bosboom et al., 2011; Salahi & Vahidinia, 2011). Such a distribution can only be explained by a seaway connecting easternmost Central Asia with the Transylvanian Basin (Fig. 5). Already, Burtman (2000) and Popov et al. (2004) referred to the Eocene Tarim Basin (China) as the easternmost part of a huge Eurasian sea extending throughout the Ferghana, Afghan-Tajik, Syr-Darya, Amu-Darya and Kopet-Dagh basins, into the Alborz basin of NE Iran (Fig. 5). This vast epicontinental sea belonging to the Tethys domain gave rise in the Oligocene to the Paratethys Sea (see Royal, 1999; Popov et al., 2004; Dercourt et al., 1993; Bosboom et al., 2014; Tang et al., 1992; Burtman & Molnar, 1993; Bosboom et al., 2015).

**Lithostratigraphic comparison of Paleogene successions in central Asian basins**

The lithostratigraphic studies of the Kalateh section permits a regional scale comparison of the Ziarat Formation in the eastern Alborz region with other parts of Alborz (Central-Western Alborz) (e.g. see Khatibi-Mehr and
Sokolowia horizon of the Ziarat Formation (eastern Alborz, Iran): biostratigraphic and paleogeographic implications

Fig. 7 a Field photographs of the “Sokolowia horizon” form the Ziarat Formation, Kalateh section (Alborz region). b-c Close-up view of densely packed of oyster concentrations and d-f shells commonly show sparse distribution.
**Fig. 8** Stratigraphic chart of Paleogene formations in different Central Asian basins, including Alborz (Aghanabati, 2004), Kopet-Dagh (Afshar-Harb, 1994), Amu Darya (Ulmishek, 2004), Afghan-Tajik (Ulmishek, 2004), Ferghana (Bande et al., 2015), Syr darya (King et al., 2013) and Tarim (Yang et al., 2013). Highlights on the stratigraphic chart show the presence of the *Sokolovia* horizon in the basins of Kopet-Dagh (Salahi & Vahidinia, 2011), Amu darya (Berrizzi Quarto di Palo, 1970), Afghan-Tajik (Berrizzi Quarto di Palo, 1970), Ferghana (Vyalov, 1935), Syr darya (Romanovski, 1880; Gorizdro, 1913), Tarim (Lan, 1997; Bosboom et al., 2011) and Alborz (present study).

Adabi, 2014; Hadi et al., 2016). Furthermore, they indicate relationship with the sequences of Khangiran Formation in the Kopet-Dagh region in the north-northeastern Iran during the early Paleogene (Figs. 6-7). At a larger scale, the Paleogene deposition in Central Asian basins often started with red continental clastics in the early Paleocene, such as Fajan Formation in Alborz, Pesteligh Formation in Kopet-Dagh and Bokhara Formation in the Amu-Darya. Red beds are also present in the some parts of Aertashi Formation in Tarim Basin (Bosboom et al., 2015) (Fig. 8). The late Paleocene sediments continue mainly with shallow carbonate deposits, as well as terrigenous rocks and anhydrite (partly Ziarat Formation in Alborz, Chehelkaman Formation in Kopet-Dagh, Suzak Formation in Amu-Darya and Lower Qimugen Formation in Tarim). At the beginning of the Eocene, the deposition continues by limestone, marly limestone and rarely silty marl in Ziarat Formation, and afterward starts with siliciclastics, such as shale, siltstone, sandstone or even silty marl, and in some places also by volcanic deposits (green tufts). Corresponding sediments are present in Karaj Formation in Alborz, Khangiran Formation in Kopet-Dagh, Alay and Turkestian Formation in Amu-Darya, and Upper Qimugen and Kalatar Formation in Tarim) (Fig. 8, e.g., see Otto, 1997; King et al., 2013; Bosboom et al., 2014; Bougeois et al., 2016). Finally, the Oligocene deposits are often represented by red continental clastics that are in most cases discontinuously located on Eocene marine deposits. They include Sumsar Formation in the former Soviet Union, Kezilouyl Formation in the Tarim Basin of China, and Lower Red Formation in the Kopet-Dagh and Alborz Basins of Iran (e.g., see Egamberdyyev & Mayvandi, 1992; Bosboom et al., 2014; Bougeois et al. 2016).

These lithostratigraphical features and macro-benthic data similarities show related paleoenvironmental histories of the Alborz, Kopet-Dagh, and the adjacent basins of Central Asian regions during the Paleogene time. On the other hand, the paleogeography, controlling mechanisms (e.g. eustasy and tectonism) and paleoenvironmental impacts of the proto-Paratethys sea in the easternmost parts from Central Asia are studied in details (see Royal, 1999; Popov et al., 2004; Bosboom et al., 2014; Bosboom et al., 2015), while the aforementioned data has not been yet properly examined in Iran. The names of known formations of Paleogene sequences in the mentioned areas are shown in Fig. 8.

**CONCLUSION**

During the middle Eocene, the Eastern Alborz region as apart of the Alpine-Himalayan orogenic system on the southern margin of the Caspian Sea was covered by shallow-marine deposits bearing high abundance larger foraminifera along with oyster bivalves. The present study provides a new insight into the Eocene sequences of the eastern Alborz region by the following results:

1.- The studied oyster bivalves *Sokolovia buhisi* morph. *buhisi* and *S. buhisi* morph. *eszterhazyi* from the Ziarat Formation in the eastern Alborz region, found on top of larger benthic foraminifera accumulations with *Nummulites lyelli*, *Orbitoclypeus zitieli* and *Asterocyclina stella stella*, are most likely Bartonian in age.

2.- The presence of *Sokolovia* key horizon in NE Iran at the crossroads between Central Asia and Southeastern Europe suggests a well-established seaway along the southern margin of a large-sized Eurasian epicontinental sea during middle-late Eocene (late Lutetian-early Priabonian).

3.- Correlation of the middle Paleogene sedimentary sequence of eastern Alborz basin with different sedimentary basins in vast areas of Central Asia strikes out similarities in their tectono-stratigraphic architecture, suggesting a related geodynamic and paleoenvironmental history shaped apparently by the Alpine-Himalayan orogenic system.
